Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

- Influence of vision on the average trajectories

- Influence of vision on the variability profiles

- “Desired-trajectory” versus optimal feedback control

Stochastic optimal control models

Conclusions

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

“Desired-trajectory” versus optimal feedback control

Stochastic optimal control models

Conclusions

Redundancy in the control of locomotion

Redundancy in the control of arm movements

Jordan and Wolpert, in *The Cognitive Neuroscience*, 1999

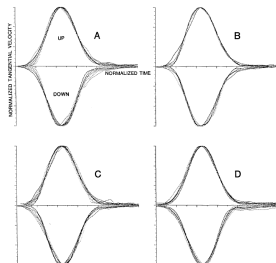

Spatial control of arm movements

Straight hand paths

Morasso, *Exp Brain Res*, 1981

Bell-shaped velocity profiles

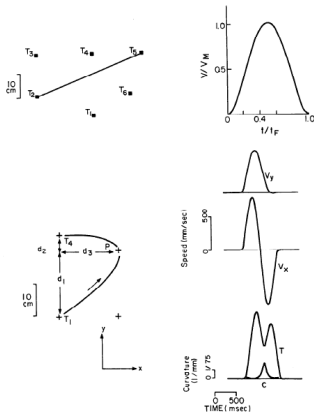

Atkeson and Hollerbach, *J Neurosci*, 1985

- Stereotypy observed only for **hand trajectories in Cartesian coordinates**
- Control in terms of Cartesian coordinates of the hand, not in terms of e.g. joint angles or muscle activity

Optimal control of arm movements

- ▶ Humans may select the hand trajectories that **minimize** a certain cost
- ▶ One popular model is the **minimum jerk** model developed by Flash and Hogan

$$\min_{x,y} \int_0^1 \left(\left(\frac{d^3x}{dt^3} \right)^2 + \left(\frac{d^3y}{dt^3} \right)^2 \right) dt$$

Typical features:

- ▶ Straight, smooth, hand paths
- ▶ Bell-shaped velocity profiles
- ▶ Inverse relationship between velocity and curvature (via-points)

Questions

- ▶ Is human locomotion controlled at the level of whole-body trajectories?
- ▶ Are locomotor trajectories optimal? According to what criteria?
- ▶ What mechanisms underly the formation of locomotor trajectories?

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

“Desired-trajectory” versus optimal feedback control

Stochastic optimal control models

Conclusions

General experimental methods

- ▶ Motion capture system: infrared cameras + light reflective markers
- ▶ Body position defined by shoulders' midpoint

Average trajectories and variabilities

- ▶ Time rescaling so that $t_0 = 0$ and $t_1 = 1$
- ▶ Definition of average trajectories and variabilities

Experiment 1: stereotypy of locomotor trajectories

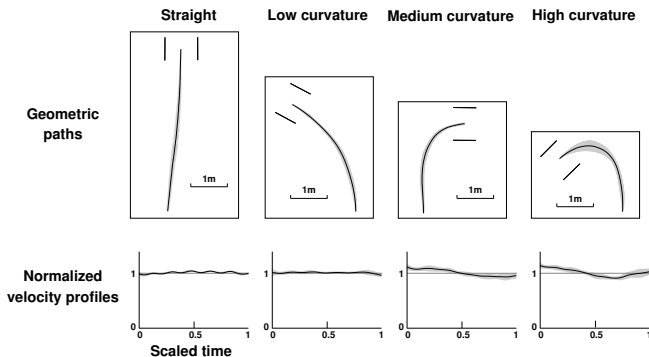

- ▶ Reminder: control of arm movements in terms of Cartesian coordinates of the hand
- ▶ What is planned and controlled in goal-oriented locomotion?
 - ▶ **Step-level**: plan and execute sequences of precise foot positions (FP), resulting in a whole-body trajectory
 - ▶ **Trajectory-level**: plan a whole-body trajectory (in Cartesian space) and implement it by appropriate sequences of foot positions
- ▶ Variability of the sequences of FP versus variability of whole-body trajectories

Experiment 1: methods

- ▶ Protocol: **walking towards and through a distant doorway** (Arechavaleta et al, 2006)
- ▶ Constraints on Initial and final positions and walking directions
- ▶ 40 targets (a target = position \times orientation)
- ▶ 6 subjects \times 40 targets \times 3 repetitions = 720 trajectories

Experiment 1: results (trajectory stereotype)

Hicheur, Pham et al, *Eur J Neurosci*, 2007

Even for HC, maximum variability was $\leq 17\text{cm}$

Experiment 1: results (foot positions variability)

- ▶ variability of the sequences of FP ($\geq 20\%$ of step length)
- ▶ variability of whole-body trajectories ($\leq 5\%$ of trajectory length)

Experiment 1: conclusions

- ▶ Goal-oriented locomotion is not planned and controlled as a sequence of precise “foot pointings”
- ▶ Rather, it is likely planned and controlled at the level of **whole-body trajectories**
- ▶ This is reminiscent of the concept of spatial control of hand movements (Morasso, *Exp Brain Res*, 1981)

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

“Desired-trajectory” versus optimal feedback control

Stochastic optimal control models

Conclusions

Context

- ▶ Reminder: minimum jerk model for hand trajectories

- ▶ Common features of hand and locomotor trajectories:
 - ▶ smoothness
 - ▶ straightness for locomotor “reaching”
 - ▶ inverse relationship between velocity and curvature
- ▶ Can the minimum jerk model also simulate locomotor trajectories?

Minimum Square Derivative models

► Minimize

$$\min_{x,y} \int_0^1 \left(\frac{d^n x}{dt^n} \right)^2 + \left(\frac{d^n y}{dt^n} \right)^2 dt$$

for $n = 1, 2, 3, 4$ (min velocity, min acceleration, min jerk, mini snap)

► subject to the constraints (initial and final conditions)

$$\begin{aligned} x(0) &= x_0, & x(1) &= x_1 \\ y(0) &= y_0, & y(1) &= y_1 \\ \dot{x}(0) &= v_0^x, & \dot{y}(0) &= v_0^y \\ \dot{x}(1) &= v_1^x, & \dot{y}(1) &= v_1^y \\ \ddot{x}(0) &= a_0^x, & \ddot{y}(0) &= a_0^y \\ \ddot{x}(1) &= a_1^x, & \ddot{y}(1) &= a_1^y \end{aligned}$$

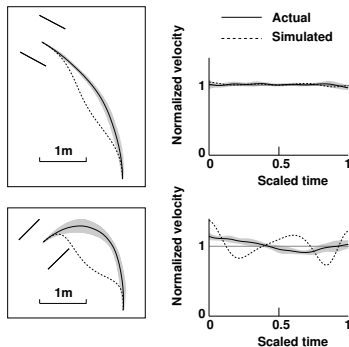

where the $x_0, x_1, y_0, v_0^x, \dots$ are extracted from the experimental data

► For $n = 3$ (min jerk), the optimal trajectory is made of 5th-order polynomials

$$\begin{aligned} x(t) &= c_5 x^5 + c_4 x^4 + c_3 x^3 + c_2 x^2 + c_1 x + c_0 \\ y(t) &= d_5 y^5 + d_4 y^4 + d_3 y^3 + d_2 y^2 + d_1 y + d_0 \end{aligned}$$

Results: minimum velocity and minimum acceleration

Minimum velocity

Minimum acceleration

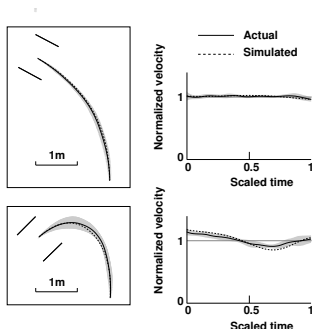

Pham et al, *Eur J Neurosci*, 2007

⇒ These models cannot simulate trajectories with large curvature

Results: minimum jerk and minimum snap

Minimum jerk

Minimum snap

Pham et al, *Eur J Neurosci*, 2007

⇒ Good simulations for all categories: the simulated trajectory always lie **within** the variance ellipses

Results: quantitative comparisons

Max trajectory simulation error

Max velocity profile simulation error

Pham et al, *Eur J Neurosci*, 2007

- ▶ Simulation error $\leq 13\text{cm}$ for min jerk and min snap, that is $\leq 4\%$ of trajectory length
- ▶ This is also smaller than the experimental variability (5%)

Conclusions

- ▶ The minimum jerk model (and also the minimum snap model) can accurately predict the average locomotor trajectories
- ▶ The formation of hand and locomotor trajectories thus may obey the same organizing principles
- ▶ This strengthens the “**motor equivalence principle**” hypothesis: “*at the higher levels of the motor system, there may exist kinematic representations of movements that are independent of the nature of the actual effector*” (Bernstein, *The co-ordination and regulation of movement*, 1967)

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

"Desired-trajectory" versus optimal feedback control

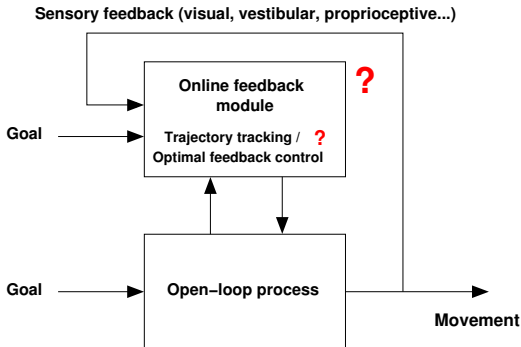

Stochastic optimal control models

Conclusions

Main assumption

Two main issues (indicated by the question marks in the classical diagram)

- Existence of online feedback control in **visual** and **nonvisual** locomotion?
- Nature of the online feedback control?

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

"Desired-trajectory" versus optimal feedback control

Stochastic optimal control models

Conclusions

Problem statement

How vision affects the average trajectories?

Experiment 2: methods

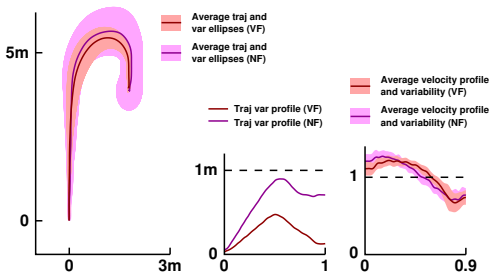

- ▶ Protocol: same as in Exp 1 with the door replaced by an arrow
- ▶ 2 conditions: **Visual (V)** vs **Nonvisual(N)**
- ▶ 14 subjects \times 2 conditions \times 11 targets \times 3 repetitions

Experiment 2: results

Visual (V) vs Nonvisual (N)

- ▶ Small differences in **average trajectories** (Distance between the two trajectories $\leq 30\text{cm}$ on average)
- ▶ Large differences in **variability profiles** (**31cm** for **V** vs **74cm** for **N**)

Experiment 2: conclusions

- ▶ Vision does not affect the average trajectories
 - ⇒ Same **open-loop** processes governing visual and nonvisual locomotion
- ▶ Vision affects the variability profiles
 - ⇒ Existence of vision-dependent **feedback** processes

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

"Desired-trajectory" versus optimal feedback control

Stochastic optimal control models

Conclusions

Problem statement

- ▶ Reminder: vision does not affect average trajectories

- ▶ How vision affects the variability profiles?
- ▶ Variability profiles in conditions **V** vs **N**

Experiment 3: methods

- ▶ Same protocol as in Exp 2
- ▶ 5 subjects \times 2 conditions (**V**/**N**)
 \times 5 targets \times 8 repetitions
- ▶ **Straight** targets: 1, 2 ; **Angled** targets: 3, 4 , 5
- ▶ **Intra-subject** analysis

Experiment 3: results

Variability profiles in conditions **V** and **N**

Pham and Hicheur, *J Neurophysiol*, 2009

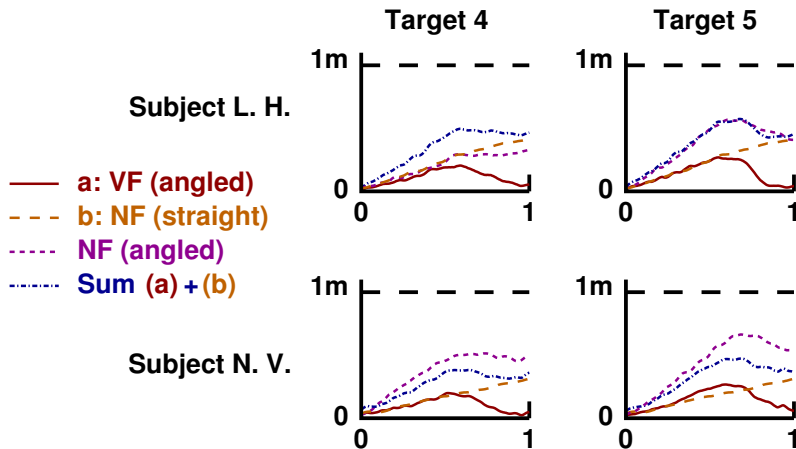

- Larger variability in N than in V
- V: **zero** variability in straight targets, **bump-shape** in angled targets
- N: **linearly increasing** in straight targets, **non-monotonic** in angled targets

Experiment 3: two-sources hypothesis

- Bump: motor-complexity-dependent, vision-independent
- Line: motor-complexity-independent, vision-dependent

Experiment 3: two-sources hypothesis, verification

Experiment 3: conclusions

- ▶ Non-monotonic profiles \Rightarrow existence of online feedback control
- ▶ Two-sources hypothesis \Rightarrow the control mechanism in condition **N** can be decomposed into:
 - ▶ a vision-independent component (bump)
 - ▶ a vision-dependent component (line)
- ▶ Bump-shape profile: interplay between execution noise and feedback control

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

“Desired-trajectory” versus optimal feedback control

Stochastic optimal control models

Conclusions

Problem statement

What is the nature of the online feedback?

- ▶ "Desired-trajectory" tracking operates in two steps
 1. Compute an optimal trajectory according to some cost
 2. Track this trajectory (correct any perturbations back to the desired trajectory)
- ▶ Optimal feedback control: no intermediate representation, optimally correct perturbations with respect to the task

Experiment 5: methods

- ▶ First session: no via-point
- ▶ Second session: 1 via-point placed on the average trajectory
- ▶ Third session: 3 via-points placed on the average trajectory

Experiment 5: results

No via-point

1 via-point

3 via-points

Variability profiles

- ▶ The simple "desired-trajectory" tracking hypothesis can be rejected
- ▶ However, sequentially tracking multiple "desired-trajectories" remains possible
- ▶ Optimal feedback control can naturally explain the variability patterns observed

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

“Desired-trajectory” versus optimal feedback control

Stochastic optimal control models

Conclusions

Context

- ▶ **Deterministic** models cannot explain **variability profiles**
- ▶ Here: **stochastic models**, more precisely some simplified **optimal feedback control** models (Hoff and Arbib, *J Mot Behav*, 1993; Todorov and Jordan, *Nat Neurosci*, 2002)
- ▶ Clarify the relationship between the control mechanisms in visual and nonvisual locomotion

Visual condition: description of the model

Basic idea of optimal feedback control:
“goal-directed corrections”

1. Discretize the movement into n steps
2. At step i , compute first a **minimum jerk** trajectory
3. Add some “signal-dependent” random perturbations to the provisional state $s'(i+1)$
4. Smoothly interpolate a new trajectory between the previous state $s(i)$ and the new perturbed state $s(i+1)$

-  Initially planned trajectory
-  Random perturbation
-  Re-planned trajectory

Visual condition: results

Pham and Hicheur,
J Neurophysiol, 2009

⇒ This model can simulate both the trajectories and the variability profiles:

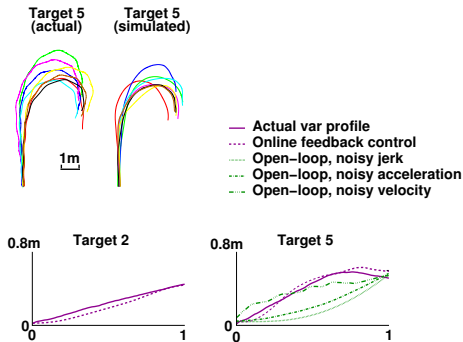

- ▶ almost **zero** in “straight” targets
- ▶ **bump-shaped** in “angled” targets

Nonvisual condition: online feedback model

- ▶ “Two-sources” hypothesis
- ▶ The first component can be simulated by the same algorithm as in condition **VI**
- ▶ The second component is related to state estimation and can be rendered by **perturbing the target** (can be discussed later)

Nonvisual condition: results

Pham and Hicheur,
J Neurophysiol, 2009

⇒ This model can simulate the variability profiles:

- ▶ linearly increasing in “straight” targets
- ▶ non-monotonic in “angled” targets

Open-loop models cannot reproduce the non-monotonic behavior

Stochastic models: conclusions

- ▶ Existence of online feedback control in **nonvisual locomotion** confirmed
- ▶ Two-sources hypothesis confirmed
- ▶ In particular: visual and nonvisual locomotion not only share the **same open-loop processes** but also the **same feedback processes**
- ▶ In nonvisual locomotion, same control mechanisms as in visual, but with respect to a **corrupted target position**

Outline

Context

Stereotypy of locomotor trajectories

Deterministic optimal control models

Control mechanisms underlying the formation of trajectories

Influence of vision on the average trajectories

Influence of vision on the variability profiles

“Desired-trajectory” versus optimal feedback control

Stochastic optimal control models

Conclusions

Summary of the results

- ▶ Locomotor trajectories are **stereotyped**. Goal-oriented locomotion is likely planned and controlled at the level of **whole-body trajectories in space**
- ▶ Locomotor trajectories are planned and controlled at a high cognitive level and, to some extent, **independently of the sensory and motor conditions** of locomotion
- ▶ Similar principles seem to underlie the formation of locomotor and hand trajectories
- ▶ A combination of optimal **open-loop** and **feedback** processes governs the formation of locomotor trajectories. The open-loop process is likely based on **minimum jerk** principle, the feedback process on **optimal feedback control**

Relations with humanoid robotics?

- ▶ Les principes de contrôle des trajectoires locomotrices humaines (contrôle au niveau de la trajectoire, minimum-jerk, optimal feedback) peuvent-ils s'appliquer pour les robots humanoïdes?
- ▶ Quel serait l'intérêt?
 - ▶ Robots plus efficaces?
 - ▶ Robots plus socialement acceptable?
